Abstract. In this article we investigate the principle and properties of a vertical passive seismic noise attenuator conceived for ground based gravitational wave interferometers. This mechanical attenuator based on a particular geometry of cantilever blades called monolithic geometric anti springs (MGAS) permits the design of mechanical harmonic oscillators with very low resonant frequency (below 100mHz).

Here we address the theoretical description of the mechanical device, focusing on the most important quantities for the low frequency regime, on the distribution of internal stresses, and on the thermal stability.

In order to obtain physical insight of the attenuator peculiarities, we devise some simplified models, rather than use the brute force of finite element analysis. Those models have been used to optimize the design of a seismic attenuation system prototype for LIGO advanced configurations and for the next generation of the TAMA interferometer.

1. Introduction

A fundamental issue in designing interferometric gravitational wave detectors is the isolation of the test masses (heavy mirrors) from environmental noise sources, such as seismic noise. It is well known that a very effective way to reduce this type of perturbation is to use mechanical harmonic oscillators, which possess the important feature of attenuating the seismic noise above their resonant frequency.

One of the major difficulties in designing this kind of system is to achieve vertical attenuation performance comparable to that obtainable in the horizontal direction. In long baseline interferometers, this is a significant issue because the vertical motion is coupled to the direction of sensitivity (horizontal direction) through mechanical imperfections, optic wedges, the earth curvature, and mirrors' orientation.

Figure 1. Schematic view of a complete MGAS filter.

A possible solution to the problem, which has been implemented in the so-called super-attenuators of the VIRGO detector [Caron *et al* 1997], is based on the magnetic anti-spring concept [Beccaria *et al* 1997].

A considerable improvement to the magnetic anti-spring is the geometric anti-spring concept (GAS) [Bertolini *et al* 1999, Cella *et al* 2002], which allows significant increases in the vertical attenuation and thermal stability of a seismic attenuation system (seismic filter).

The monolithic geometric anti-spring (MGAS) concept introduced by one of the authors is essentially an evolution of the GAS concept capable to significantly improve the GAS system performance.

A seismic attenuation system based on the MGAS concept is better than the equivalent GAS system mainly because of its simplicity. In fact, this characteristic allows removal of several mechanical parts that introduce unwanted low frequency resonances responsible for reducing the filtering efficiency on all the degrees of freedom.

In the next sections we address the theoretical description of the MGAS, and some of the main issues related to the design of a seismic filter.

2. Low Frequency One Dimensional Model

An MGAS configuration is made of several quasi-triangular blades radially disposed and connected together at their vertices (see Figure 1).

Taking advantage of this radial symmetry, the MGAS physics can be studied considering just a single blade. Moreover, because of the blade's symmetry along a vertical plane (called Oxy as shown Figure 2), and the typical blade dimensions (thin

blade approximation), we can reduce the dynamics to one of a simple single degree of freedom system.

Figure 2. Reference Frame for the MGAS study. The curvilinear coordinate l is measured from the point O and the component F_x , and F_y represent the external forces applied to the blade

The blade's base is clamped to a massive structure and subjected to an external force on the tip due to the load and to the other radially arranged blades. The horizontal component compresses and bends the blade longitudinally.

In the low frequency regime, below the internal mode frequencies, the dynamics is dominated by the clamping structure mass (much greater than the blade's mass, which we can neglect) and by the load.

The blade has a constant thickness d much smaller than the two other dimensions, a length L and a variable transverse width $w(l)$, with $l \in [0, L]$. The variable l is the curvilinear coordinate following the intersection of the blade's neutral surface with the plane Oxy , i.e. the neutral axis of the blade. It is also convenient to define $\theta(l)$ as the angle between the tangent of the curvilinear coordinate and the x axis.

Under these approximations, we can model the thin blade as a massless elastic line with a potential energy [Landau, Lifshitz 1959]

$$U = \int_0^L \left\{ \frac{1}{2} EI(l) \left[\frac{d\theta(l)}{dl} \right]^2 - F_x \cos \theta(l) - F_y \sin \theta(l) \right\} dl. \quad (1)$$

F_x and F_y , are respectively the horizontal and vertical external forces applied to the blade's tip, and I is the transverse moment of inertia of the blade, $I = w(l)d^3/12$. The mechanical characteristics of the blade material enter just through the Young's modulus E .

It is convenient to rewrite the potential energy in the following way

$$U = \frac{Ed^3w(0)}{12L} \tilde{U}, \quad (2)$$

where

$$\tilde{U} = \int_0^1 \left\{ \frac{1}{2\gamma(\xi)} \left[\frac{d\theta(\xi)}{d\xi} \right]^2 - G_x \cos \theta(\xi) - G_y \sin \theta(\xi) \right\} d\xi, \quad (3)$$

and $\gamma(x) = w(0)/w(x)$ is a normalized blade's shape function, $\xi = l/L$. The quantities G_x, G_y are dimensionless parameters proportional to the horizontal compression and to the vertical load:

$$G_i = \frac{12L^2}{Ed^3w(0)} F_i, \quad i = x, y. \quad (4)$$

Writing U in such a form we make clear that the nonlinear behavior of the blade (the $\tilde{U}$ term) is parameterized by the dimensionless parameters G_i , which completely defines the “working point” of the system for a given normalized shape of the blade $\gamma(\xi)$. Every physical quantity we are interested in will be indeed written as a product of two terms. The first is an appropriate dimensional scale factor, a simple combination of the blade's parameters. The second is a function of the G_i only (for a given shape of the blade), and must be numerically evaluated. This means that the solution corresponding to a particular pair (G_x, G_y) can be used to describe a large class of different physical systems, obtained one from the other by a transformation of the parameters which leaves G_x and G_y both unchanged. For example, the vertical position Y of the blade's tip can be written as

$$Y = L \int_0^1 \sin \theta(\xi) d\xi = L y(G_i). \quad (5)$$

Scaling the blade length L by a factor λ , and multiplying the blade's thickness d by a factor $\lambda^{2/3}$, we keep the working point unchanged. This is very useful in order to plan the integration of the blade into a new system [Bertolini 2003].

2.1. Integration of the Equation of Statics and General Properties

Computing the variation $\delta\tilde{U}$ of the action (3) with respect to θ to minimize the potential energy, we obtain the equation of statics for the physical system in the presence of an assigned external load G_i . Then, rewriting δU as a system of first order differential equations we get

$$\frac{dp}{d\xi} = G_x \sin \theta(\xi) - G_y \cos \theta(\xi), \quad (6)$$

$$\frac{d\theta}{d\xi} = \gamma(\xi) p, \quad (7)$$

with boundary conditions

$$\theta(0) = \theta_0, \quad \theta(1) = \theta_1 \quad (8)$$

Because this is a boundary value problem, in general the solution uniqueness cannot be guaranteed. Different equilibrium configurations can coexist for the same values of boundary conditions and parameters. This can be easily seen in the particular case

of constant blade width. In this case, $\gamma = 1$ and the system admits a ξ -independent quantity A that can be written as

$$A = \frac{1}{2} \left(\frac{d\beta}{d\tau} \right)^2 + (1 - \cos \beta) \quad (9)$$

where we set $\beta = \theta - \psi$, $G = \sqrt{G_x^2 + G_y^2}$, $\tau = \sqrt{G}\xi$ and $\tan \psi = G_y/G_x$. This is formally equivalent to the energy of a simple pendulum and we will discuss now the behavior of our system from a qualitative point of view, looking at the corresponding phase diagram depicted in Figure 3. In Appendix B we give some details about the analytical solution of this problem.

Figure 3. Evolution of the blade's angle in the phase space, for a blade of constant width. The phase space is equivalent to the one of the simple pendulum: closed trajectories correspond to a bounded variation of the blade's angle, open ones to blade's configurations with turns. Different solutions which satisfy the boundary condition for $\beta(0) = \beta_0$ and $\beta(\sqrt{G}) = \beta_1$ are depicted: solution Γ_i starts in S_i and ends in E_i . We assume periodic boundaries in β : Γ_1 starts in S_1 and after a complete 2π cycle moves to E_1 . See Section 2.1 and Appendix B for a full discussion.

Our formal “pendulum” is allowed to evolve only in a well defined interval of the “time” parameter, that is $\tau \in [0, \sqrt{G}]$. During this interval the system must move from a starting point on the $\beta = \beta_0$ line to a final point with $\beta = \beta_1$. We can freely choose

our starting point on the line $\beta = \beta_0$. Different possibilities correspond of course to different values of A .

Suppose that we start on the boundary of the oscillatory region (the S_0 point in Figure 3). Then, we find the first solution Γ_0 when G is large enough to allow the end point to be in E_0 . This is a very simple configuration, with a monotonically increasing value of θ . If we now keep G constant and increase p at the starting point we obtain a motion which is faster and faster, and a longer and longer trajectory. When p is big enough, the trajectory will end at $\beta = \beta_1 + 2\pi$, describing a new solution Γ_1 with the same parameter G as the old one. Clearly, with this method we can generate an infinite set of solutions Γ_k , which differ in the number of times the blade's angle makes a complete turn. Configurations with turns can potentially give good working points (see for example [Winterflood and Blair 1998]), but we are not interested in these in this work.

Another possibility is the existence of “undulated” configurations. Inside the oscillatory region of the phase diagram we can construct solutions with the same (large enough) value of G , which can be classified according to the number of zero curvature points (crossings of the $\dot{\beta} = 0$ axis in the phase diagram). To make this plausible we can consider a solution with some starting point S_3 (see Figure 3) and a very large G , such that it makes N turns in the phase diagram. When we move S_3 towards the boundary of the oscillatory region, we should find at least $2N$ solutions. The reason is that on the boundary the solution is without crossings, because the time required to approach the point $\dot{\beta} = 0$ is infinite. So the trajectory must “unwind” when we move S_3 , and its end point must cross the $\beta = \beta_1$ line at least $2N$ times. Connected with the existence of “undulated” configurations is the possibility of buckling-type phenomena^{††}. As we will see, this is in fact the key to understanding the behavior of our system, as will be discussed extensively in the following section.

2.1.1. Effective Potential To study the solutions of Equations (6) and (7) as a function of the parameters, it is convenient to apply the so-called continuation method. We use the AUTO2000 code, which implements several algorithms for continuation of differential and algebraic problems. Details can be found in the user's manual [Doedel *et al* 2000].

The basic strategy consists in the exploration of the solution space when smoothly changing the values of the coordinates of the blade's tip, the horizontal position

$$x \equiv \frac{X}{L} = \int_0^1 \cos \theta(\xi) d\xi \quad (10)$$

or the vertical position defined in Eq. (5).

Using the continuation method we constructed the plot in Figure 4, which is a graphic representation of $G_y(x, y)$. In the explored region, it appears that this is a well defined single-valued function as suggested by physical intuition. In fact, numerical

^{††}See [Winterflood *et al* 2002] for a different approach to vertical seismic attenuation, based on a buckling behavior.

Figure 4. The normalized vertical position y versus normalized horizontal position x of the blade's tip, for different values of the vertical dimensionless load G_y . For a generic value G_y there is a folding singularity where a couple of solutions vanish, and a stable branch. In the special case $G_y = G_y^*$ (here $G_y^* \simeq 1.6895$) we obtain a two sided bifurcation with a turning point. This is depicted schematically in the lower square (bold lines), emphasizing its difference from the simpler pitchfork singularity depicted in the upper square. See Subsection 2.1.6 for a full discussion of these diagrams.

investigation using AUTO2000 gives no evidence of bifurcations. We can repeat a similar study to obtain a representation of the function $G_x(x, y)$ in the same region. We do not show the relative diagrams because they do not present peculiar features, but the final conclusions are that both G_x and G_y are regular and single-valued functions of the blade's tip coordinate. We can expand them in small variations of the parameters around the chosen working point

$$G_i(x, y) = G_i^{(0)} + K_{ij}\delta_j + \frac{1}{2}K_{ijk}\delta_j\delta_k + \frac{1}{3!}K_{ijkl}\delta_j\delta_k\delta_l + O(\delta_i^4) \quad (11)$$

where $\delta_x = x - x_0$ and $\delta_y = y - y_0$. As G_i are the components of the external force acting on the system, it is natural to ask if they can be written as the partial derivatives of an effective potential function

$$G_i(x, y) = \frac{\partial U_{eff}(x, y)}{\partial x_i}. \quad (12)$$

On physical grounds, the answer should be positive. In fact, this potential energy represents the energy stored in the system by the external work, and because there is

no dissipation in our model, it should be a well defined function of the position. If U_{eff} were multivalued, the difference between two of the energy values could only be interpreted as the difference between the energy stored in two different configurations with the same x, y values. But in this case a closed path in the (x, y) space crossing a bifurcation point should exist. If U_{eff} exists the integrability conditions tell us that the coefficients $K_{...}$ are completely symmetric in their indices.

A comment about the general validity of these results is in order. As we discussed, it is possible that many solutions with the same values of x and y exist, so Equations (11) should be understood as a perturbative expansion around some well defined blade configuration. In practice, this all we need. With this restriction all should work well, unless we try to expand around a bifurcation point (that is, a point where the number of solutions changes).

All the quantities we are interested in can be recovered from the coefficients $K_{...}$, which are partial derivatives of the effective potential evaluated at the working point. It is quite important to find a good method to monitor these quantities during the continuation procedure. This can be done by introducing auxiliary functions, governed by appropriate differential equations that must be added to the basic relations (6), (7) and (8). The method is explained in detail in Appendix A: here we stress only that for a given order in the expansion of the effective potential we obtain a finite system of differential equations to solve.

As a final observation, we recall that the assumption of the existence of an effective potential is not mandatory in order to calculate the coefficients $K_{...}$. In fact, the integrability conditions translate into a set of nontrivial relations between the auxiliary functions which can be used to test or simplify the numerical code (see Appendix A).

We will give other details about the continuation method in Subsections 2.1.2 and 2.1.3, explaining its application to the search for configuration with a low vertical stiffness. For more information, good starting points are [Doedel *et al* 1991, Doedel *et al* 1991b] and references therein.

2.1.2. Vertical Position of the Blade's Tip To give a simple example of application of the continuation method, we will study the normalized blade tip's vertical position.

Here and in the following we will present results for a particular configuration with $\theta_0 = \pi/4$, $\theta_L = -\pi/6$ and $\gamma^{-1}(\xi) = c_1 + c_2 \cos \beta \xi + c_3 \sin \beta \xi$, with $c_1 = -0.377$, $c_2 = 1.377$, $c_3 = 0.195$ and $\beta = 1.361$. The particular shape of the blade was chosen to compare with measurements taken on a prototype which will be published elsewhere [Sannibale *et al* 2004]. In Subsection 2.1.6 we will comment on the general validity of our conclusions.

If we choose as independent parameters the vertical load G_y and the tip's horizontal position x , we can construct the diagram in Figure 5. There the possible equilibrium values of y are plotted as a function of the vertical load, for different values of x , in an "interesting" region.

It is evident that the curves can be grouped in two different families, one made of

monotonically increasing functions of G_y (continuous line curves, corresponding to large values of x) and the other made of curves showing a couple of folding singularities (dashed line curves, folds marked with circles). The boundary between these two different families corresponds to $x = x^* \simeq 0.9027$.

A folding singularity can be detected during the continuation procedure performed by AUTO2000. After the detection it is possible to add a second free parameter and to continue the fold. This is very convenient to determine the locus of all the folding singularities.

When $x > x^*$ there is only a single equilibrium position y_0 for each value of the vertical load, and as $\partial y / \partial G_y > 0$ we can conclude also that the equilibrium is stable. If we adiabatically reduce x , the blade's y will remain at the assigned vertical load: y_0 will increase if $G_y > G_y^* = -1.6895$ and it will decrease otherwise.

When $x < x^*$ it becomes possible to have more than one equilibrium configuration: in that case two new solutions y_1 and y_2 appear, and by checking the sign of $\partial y / \partial G_y$ it is easy to see that only the largest and the smallest among y_0 , y_1 , y_2 are stable. The system can switch between these if driven by a large enough external perturbation, and we conclude that the region $x < x^*$ is associated with a bistability. The presence of this bistability can be described also by observing that the system can show a kind of hysteresis behavior. This is also illustrated in Figure 5: suppose we prepare the system in a configuration which corresponds to the point (a). If we start to increase the load adiabatically, we observe that the vertical blade tip's position increases smoothly, moving along the curve, until the fold singularity (b) is reached. At that point the system cannot respond anymore in a smooth way to a further increase of the load: it will switch abruptly to the only available equilibrium position (c). Of course the switch between (b) and (c) points is a dynamical process and depends on the system inertia. It cannot be described without solving the nonlinear equation of motion including dissipation mechanisms. Our static analysis only shows that when the equilibrium is reached the system must be settled in (c).

If now we reduce the load, the system moves smoothly along the new curve until it reaches the folding point (d). A further load reduction triggers a switch to the point (a), completing the cycle.

2.1.3. Vertical Resonance Frequency A very important parameter of an MGASF filter is the angular frequency ω_y of the fundamental vertical mode. For symmetry reasons it is evident that during the filter's vertical motion the horizontal position of the blade's tip is fixed, so the equations which define our problem are (6) and (7), supplemented by the two fixed boundary conditions (8) and by the geometrical constraint (10). The external parameters are G_y and x , while G_x is fixed by the constraint.

It is easy to see that in the frequency domain, and for low frequency,

$$\frac{L}{g} \omega_y^2 = \frac{1}{F_y} \left(\frac{\partial F_y}{\partial y} \right)_x = \frac{1}{G_y} \left(\frac{\partial G_y}{\partial y} \right)_x = \frac{K_{yy}}{G_y}. \quad (13)$$

Figure 5. The normalized vertical position y of the blade's tip versus the dimensionless vertical load parameter G_y (see Eq. 4). Each curve corresponds to a different fixed horizontal position x of the blade's tip (the x value is shown above each single curve). Two different classes of curves can be distinguished. For a curve in the first class (depicted with a continuous line) the vertical position is always an increasing function of the load, so that each point defines a stable equilibrium point for the system. For a curve in the second class (depicted with a dashed line) there is also a region, where y decreases with G_y , of unstable equilibrium points. This unstable region is separated from the stable one by a couple of folding singularities. The continuous folded curve, which corresponds to $x = 0.9027$ in this example, separates the two regions. The oriented closed path shows a typical hysteresis path, and is discussed in Subsection 2.1.2. Note that the two stable equilibrium positions in the bistable region correspond to different vertical positions of the blade's tip. Boundary conditions are always $\theta_0 = \pi/4$ and $\theta_L = -\pi/6$.

In other words, the MGAS filter is indeed formally equivalent to a simple pendulum with effective length

$$L_{eff} = LG_y \frac{1}{\left(\frac{\partial G_y}{\partial y}\right)_x}. \quad (14)$$

For the optimization of filter performance, we are interested in obtaining the smallest possible value of ω_y . As already stated, this can be obtained by simply increasing L_{eff} while keeping the working point G_i fixed. A possible transformation that performs this task is a rescaling of the blade length by a factor λ

$$L \rightarrow \lambda L, \quad \frac{F_{x,y}}{Ed^3w(0)} \rightarrow \frac{1}{\lambda^2} \frac{F_{x,y}}{Ed^3w(0)} \quad (15)$$

which changes the frequency accordingly with

$$\omega_y \rightarrow \frac{1}{\sqrt{\lambda}} \omega_y. \quad (16)$$

The vertical frequency of the blade decreases only with the square root of the blade length. A long blade is quite difficult to integrate into a real system, and its internal resonances start to reduce attenuation performance at low frequency. For these reasons we are interested in working points where L_{eff} diverges to infinity. These are the points of the parameters space where the linearized response of the system is large, or in other words where the coefficient K_{yy} of the effective potential goes to zero.

To describe the typical situation we are looking for, let's re-analyze Figure 5. From Equation (14) it is evident that the effective length of the system is inversely proportional to the slope of a curve at the considered equilibrium point. This means that in a folding singularity, $G_y = G_y^{(fold)}(x)$, the effective length diverges and so $\omega_y \rightarrow 0$. Another point where $L_{eff} \rightarrow \infty$ is on the boundary curve $x = x^*$, for the particular value $G_y = G_y^*$ which corresponds to a vertical slope.

Setting the parameters of our system “near” one of these critical points, we can obtain a vertical resonance frequency as small as we want in principle. However, there is a qualitative difference between the critical points on a folding singularity $(x, G_y^{(fold)}(x))$ and the critical point on the boundary curve (x^*, G_y^*) .

This difference can be fully appreciated by looking at Figure 6. Here the square of the vertical resonance frequency in g/L units is plotted versus the vertical load parameter, for different x values. In this picture it is easy to distinguish between the regions of stable equilibrium points ($\omega_y^2 > 0$) and the unstable one ($\omega_y^2 < 0$). An intersection between a curve and the axis $\omega_y^2 = 0$ corresponds to a folding singularity in Figure 5.

We can choose the working point near this intersection, in the stable region: however in this case a load fluctuation can easily drive the system into the unstable region, and this is dangerous because we are in a bistable regime. On the contrary the critical point on the boundary curve corresponds in the plot to the cusp on the $\omega_y^2 = 0$ axis. If we choose our working point near this, on a fully stable curve $x = x^* + \delta_x$, $\delta_x > 0$, it cannot be driven by a load fluctuation into the unstable region. Of course, a fluctuation of x

Figure 6. Vertical frequency dependence versus load, near the minimum frequency working point. The vertical axis is the squared angular frequency of the vertical oscillation, in the low frequency approximation, expressed in units g/L . Each curve is labeled by its x value. Dashed curves correspond to $x > x^*$, continuous ones to $x < x^*$. The bold curve, with a cusp at $\omega_y = 0$, is the boundary between the folded and unfolded region. The same hysteresis cycle of Figure 5 is plotted, with the same labels (a, b, c, d) . In the upper left corner we plot a detailed view of the region around the frequency minimum.

(which can be generated by a horizontal motion of the blade's tip) can drive our system into the unstable region, but in principle this is less dangerous because we don't have bistability in this region and the system should fall back to the original point after the fluctuation. This does not mean that there are no problems. The main issue here is the effect of the nonlinearities that unavoidably appear in systems with stiffness approaching to zero. This is discussed in section 2.1.4.

We can parameterize Figure 6 with the $K_{...}$ coefficients. Looking at Figure 5 we see that in the region of interest G_y is accurately described by a cubic function of y with coefficients that depend on x . If we take as reference point (x^*, G_y^*) and neglect corrections in δ_x we can write

$$G_y = \frac{1}{6}K_{yyyy}\delta_y^3 + G_y^* \quad (17)$$

and for the frequency

$$\frac{L}{g}\omega_y^2 = \frac{\frac{1}{2}K_{yyyy}\delta_y^2}{G_y} \quad (18)$$

eliminating δ_y we finally get near the working point

$$\frac{L}{g}\omega^2 = \frac{K_{yyyy}^{1/3}}{2} \frac{[6(G_y - G_y^*)]^{2/3}}{G_y^*} \quad (19)$$

where the cusp singularity is evident. Using the same procedure we can obtain a general relation, more involved, which reproduces quite accurately Figure 6 for small enough $\delta_x \neq 0$.

It is interesting to add some considerations about the bistable regime, drawing the same hysteresis cycle we discussed in Subsection 2.1.2. Looking at Figure 6 it is evident that jumps are located at the edge of the unstable region, and the two stable equilibrium points correspond not only to a different blade tip vertical position, but also to a different value of the vertical resonance frequency. An exception is, for example, the point D .

2.1.4. Nonlinearities In Section 2.1.3 we saw that from the point of view of system stability the critical point on the boundary curve (x^*, G_y^*) should be preferred over the critical point near a folding singularity. There is another good reason of choosing (x^*, G_y^*) . The fundamental peculiarity of the MGAS is that the variation of the stiffness with the position is in principle not negligible. This means that around the working point we have to introduce higher order corrections to the effective potential. Fixing our attention on the vertical motion only, and imposing $\delta_x = 0$, we obtain

$$G_y = K_{yy}\delta_y + \frac{1}{2}K_{yyy}\delta_y^2 + \frac{1}{6}K_{yyyy}\delta_y^3 + \dots \quad (20)$$

which clearly shows the coefficients connected to the anharmonicity.

To quantify anharmonic effects we use the ratio between the first nonlinear and linear term in the potential

$$\rho_1 = \sigma \frac{K_{yyyy}}{K_{yy}} = \sigma \left(\frac{\partial^2 G_y}{\partial y^2} \right)_x \left(\frac{\partial G_y}{\partial y} \right)_x^{-1} \quad (21)$$

where the presence σ , with $\sigma = A/L$, reminds us that the importance of nonlinearities depends on the amplitude of the motion A . Using Equation (13) and changing the independent variables to x, G_y we can rewrite this quantity as

$$\rho_1 = \sigma \frac{L}{g} \left[\omega_y^2 + G_y \left(\frac{\partial \omega_y^2}{\partial G_y} \right)_x \right] \quad (22)$$

and its behavior for small oscillation frequency can be discussed looking at Figure (6). Near (x^*, G_y^*) both terms go to zero, so the working point which minimizes the nonlinear effects is near the minimum of the curve. To first order, we must set $K_{yyyy}^* \delta_y + K_{yyyx}^* \delta_x = 0$, where δ_i are the displacements from the critical point and $K_{...}^*$ the expansion coefficients of the effective potential around it. Near a fold, however, only the first term goes to zero, and even worse, the second term increases without limits. So we expect huge nonlinear effects near a folding point, and a configuration near (x^*, G_y^*) should clearly be preferred.

For finite values of frequency the more linear configuration does not coincide with the configuration that minimizes the frequency variation with the load. The reason is that a load variation changes both the working point and the inertia seen by the blade, and only the first effect is connected to nonlinearities.

We conclude this section with an estimate of the importance of higher order nonlinearities. The ratio between the second order nonlinear term in the potential and the linear term gives

$$\rho_2 = \sigma^2 \frac{K_{yyyy}}{K_{yy}} \simeq \sigma^2 \frac{K_{yyyy}^*}{G_y} \left(\frac{g}{L \omega_y^2} \right) \quad (23)$$

which is dangerous because the numerator no longer goes to zero near the singularity. This result expresses the fact that when the vertical stiffness of the system goes to zero some kind of nonlinearity necessarily becomes dominant, and only the cubic term in the effective potential, proportional to its asymmetry, can be avoided.

This can be seen as a lower limit on the vertical frequency obtainable, which we expect to be quite small in a concrete situation, because it is proportional to σ^2 :

$$f > \frac{\sigma}{2\pi} \sqrt{\frac{g}{L} \frac{K_{yyyy}^*}{G_y}}. \quad (24)$$

As an indication, for a blade with $L = 30 \text{ cm}$, a coefficient $K_{yyyy}^* \simeq 10^3$ estimated from a typical working point and an indicative amplitude for the motion $A \simeq 10^{-3} \text{ m}$, we get $f > 10^{-1} \text{ Hz}$, which seems quite reasonable. The coefficient K_{yyyy} is of course not the same for all the critical points, so it seems reasonable to find the best configuration from this point of view, if needed.

Figure 7. Sketch of geometric blade variations induced by a temperature change. The angle of the blade's tip is fixed due to the constraint of the other blades in the MGAS. L_1 and L_2 are the distances between each clamp and a fixed vertical reference axis placed in the center of the filter. Those distances change with the temperature according to the thermal expansion coefficients α_1 , α_2 of the clamp materials. X is the horizontal length of the blade.

2.1.5. Thermal Stability The temperature dependence of the blade equilibrium position depends on the mechanical and thermodynamical parameters of the material, i.e. the thermal expansion coefficient and the variation of Young's modulus with the temperature. A sketch showing how temperature affects the blade's geometry is shown in Figure 7.

Choosing the geometrical and mechanical parameters $L_1^{(0)}, L_2^{(0)}, \alpha_1, \alpha_2$ as shown in Figure 7, we have that $x = X/L$ changes linearly with the temperature according to the following law

$$x = x_0(1 + \alpha_x \Delta T), \quad (25)$$

where α_x , is an effective thermal expansion coefficient defined by the following formula

$$\alpha_x = \frac{L_1^0 \alpha_1 - L_2^0 \alpha_2}{L_1^0 - L_2^0} - \alpha, \quad (26)$$

with α the thermal expansion coefficient of the blade's material. For example, if we choose $\alpha = \alpha_1 = \alpha_2$ (supports and blade made out of the same material) we obtain $\alpha_x = 0$.

To first order, the material dependence on temperature enters through Young's modulus. In fact, we can write

$$E = E_0(1 + \alpha_E \Delta T), \quad (27)$$

where α_E is a constant coefficient. Using the definition (4) we obtain the effective thermal expansion coefficient for G_i :

$$\alpha_G = -(2\alpha + \alpha_E). \quad (28)$$

The Typical value for stainless steel expansion coefficient at ambient temperature is $\alpha \simeq 1 \times 10^{-5} K^{-1}$. Common values for α_E are negative and of the order $10^{-4} K^{-1}$ [articolo NIM]. Accurate values strongly depend on temperature and on the alloy. This means that α_G is positive and dominated by the Young's modulus variation coefficient.

It is possible to tune α_E both in amplitude and sign in a quite large range (say, $\alpha_E \in [-10^{-4} K^{-1}, 10^{-4} K^{-1}]$) by changing alloy composition and/or using thermal treatments [SMC 2003]. Such special alloys can be used indeed, to minimize temperature dependence of the working point.

An interesting question is whether it is possible to find configurations which are insensitive to the temperature changes for a given set of coefficients α_i . As our main issue is to obtain a system with a small vertical frequency we will limit our study to an understanding of the thermal behavior of monolithic blade near a good working point.

We start with the dependence of the vertical position Y of the blade's tip as a function of the temperature. The first order variation of the vertical position due to the temperature is controlled by the quantity

$$\frac{dY}{dT} = \alpha Y + L \frac{dy}{dT} \quad (29)$$

which as we can see is the sum of two contributions. The first term accounts for the simple thermal expansion of the blade length. The second term is the “anomalous” contribution connected to the fact that the system is displaced from the working point by the temperature variation. Choosing as independent variables x and G_y (see Appendix A) we can write

$$\frac{dY}{dT} = \alpha Y + Lx \left(\frac{\partial y}{\partial x} \right) \alpha_x + LG_y \left(\frac{\partial y}{\partial G_y} \right) \alpha_G = L (y\alpha + \gamma_x \alpha_x + \gamma_G \alpha_G) \quad (30)$$

The coefficient γ_G can be rewritten as

$$\gamma_G = \frac{g}{L\omega_y^2} \quad (31)$$

and it is quite dangerous, because it diverges near the critical points. This is very reasonable physically, because when the vertical stiffness of the blade becomes very small we can expect a strong sensitivity to the variation of blade parameters. One possible way to compensate for this effect is to properly tune the parameters in equation (30). We can adjust the term proportional to α by changing y , which is connected to the boundary conditions for the blade. As we will see in Subsection 2.1.6 there is a wide range of values for the y parameter, positive and negative, compatible with a critical point.

The term proportional to α_x , as discussed previously, can be tuned with an appropriate filter design. We can estimate its importance by looking at the left diagram in Figure 8. There the relevant quantity $\partial y / \partial x = x^{-1} \gamma_x$ is plotted versus G_y for different x values in the stable region near the critical point (x^*, G_y^*) (compare with Figure 6). It is evident that the rapid variation of this parameter around the critical point is particularly relevant when we are very near to it ($x \simeq 0.903$, bold curve). This means

Figure 8. Coefficients related to thermal stability. On the left side the quantity $(\partial y/\partial x)_{G_y}$ is plotted as a function of the load parameter G_y , for different values of x chosen near the critical point. On the right side we plot $\omega_y^{-1}(\partial\omega_y/\partial x)_{G_y}$, as a function of the same parameters of the left side. See Section 2.1.5 for explanations.

that it is surely possible to tune this parameter, but also that the tuning could be very delicate.

Another important parameter, which should be made as much stable as possible, is the vertical oscillation frequency. We can define an effective “expansion” coefficient for it in the following way:

$$\alpha_\omega = \frac{1}{\omega_y} \frac{d\omega_y}{dT} = \left[\frac{x\alpha_x}{\omega_y} \left(\frac{\partial\omega_y}{\partial x} \right) + \frac{G_y\alpha_G}{\omega_y} \left(\frac{\partial\omega_y}{\partial G_y} \right) - \alpha \right]. \quad (32)$$

There are two quantities which depend on the working point in this expression. The first one is proportional to α_x , which depends on the filter design, and to the variation of the logarithm of the vertical frequency with x , which we can rewrite as

$$\frac{1}{\omega_y} \frac{\partial\omega_y}{\partial x} = -\frac{1}{2} \frac{G_y}{\gamma_G} \left(\frac{\partial^2 y}{\partial G_y \partial x} \right) \quad (33)$$

This contribution depends fully on the nonlinearity of the system. The quantity (33) is plotted on the right side of Figure 8 as a function of G_y , for several x values chosen near the critical point.

The second working-point-dependent quantity is proportional to the variation of the frequency with the load. We met this quantity when we discussed nonlinear effects, and we saw that it can be set to zero by fixing the working point near one of the minima of Figure 6. Here the derivative is weighted with ω_y^{-1} , so the situation is a bit different. As the minima of ω_y are also minima for $\log \omega_y$ it is always possible to set the contribution (33) to zero. However, as we approach the critical point its variation will become very large. As for the vertical variation of the blade's tip, this means that the tuning of α_ω will be possible but delicate, especially very near to the critical point. The method used to evaluate all of the quantities that appears in these expressions is explained in Appendix A.

2.1.6. Universality of the Results An important point is the robustness of the critical behavior of a monolithic blades. We want to understand what is the range for the “general design” parameters (tip angle, base angle and shape of the blade) which are compatible with the existence of a critical point. In order to do that we need a precise characterization of the “interesting” working point, that could be used to explore the parameter space.

This characterization is provided by Figure 5, where it is apparent that when $(x, y) = (x^*, y^*)$ we have both

$$\left(\frac{\partial G_y}{\partial y} \right) (x^*, y^*) = K_{yy}^* = 0 \quad (34)$$

and

$$\left(\frac{\partial^2 G_y}{\partial y^2} \right) (x^*, y^*) = K_{yyy}^* = 0. \quad (35)$$

How can these conditions be extracted from Figure 4 on page 7? The curves there were obtained by continuing the solution in the x parameter, at a fixed G_y and with free y . We recognize that $K_{yy} = 0$ when the slope of the depicted curves goes to infinity. This is a folding singularity that can be identified and continued adding a new free parameter, for example G_y , obtaining a locus of points where the Equation (34) is satisfied. If, following this locus, we find another folding singularity, clearly there also Equation (35) becomes true. In this way the general strategy that can be used to explore the subspace of interesting working point is clear in principle: add another free parameter and continue the new fold. Our implementation of the method was a bit different because with AUTO2000 it is not possible to continue a fold of a locus of folds. It is based on the use of the auxiliary functions introduced in Section Appendix A, but in any case give us equivalent results. For each working point we know the value of all the parameters, and of course the solution for the equilibrium equations. Monitoring the auxiliary functions we can also determine to a given order the effective potential's coefficients $K_{...}$, to get more quantitative information.

Our preliminary tests show that there is a wide range of parameters where the MGAS concept is effective. This can be seen in Figure 9, which can be used to

understand the dependence of the working point on the blade base and tip angles. For a given pair of angles θ_0, θ_1 a working point exists only inside the admissible region delimited by the upper and lower bold boundaries. Inside the admissible region we can read the values of G_y and $1 - x$ by following the continuous and dotted contour lines. It is apparent that a very large range of possibilities exists, though probably very low values of G_y will not really be useful.

Coming back to Figure 4 on page 7 we note that the point (x^*, y^*) where the four bold branches with $G_y \simeq -1.6895$ connect together is special. It is clearly a saddle point for G_y , and this tells us that the gradient of G_y is zero, which means

$$K_{yy}^* = 0 \quad (36)$$

and also

$$K_{yx}^* = K_{xy}^* = 0 \quad (37)$$

If the tangent to the curve at that point were vertical we could classify (x^*, y^*) as a so called “pitchfork” bifurcation point [Iooss and Joseph 1990, Arnold 1996], which is depicted schematically, with bold lines, in the upper right box. In the same box the dashed curve represents the locus of points where $K_{yy} = 0$, while the locus of points where $K_{yyy} = 0$ is a horizontal continuous line which overlaps with the bold one. This means that the “interesting” working point is coincident with the “pitchfork” bifurcation point.

However, a careful inspection reveals that what we really have a “two-sided bifurcation with a turning point”. This one is depicted schematically in the lower right box of Figure 4, emphasizing its different character. From this Figure we see that in this case the intersection between the dashed zero $K_{yy} = 0$ curve and the continuous $K_{yyy} = 0$ one does not correspond anymore to the singularity. More precisely we can expand G_y around the crossing point for the bold lines, obtaining up to the first order in δ_x

$$G_y - G_y^* = \frac{1}{6} K_{yyyy}^* \delta_y^3 + \frac{1}{2} (K_{yyyx}^* \delta_x + K_{yyy}^*) \delta_y^2 + K_{yyx}^* \delta_x \delta_y \quad (38)$$

where in the pitchfork case (but not in ours) $K_{yyy}^* = 0$. Setting $G_y - G_y^* = 0$ we obtain the equation for the bold lines in the diagrams, while taking the first and the second derivative of Eq. (38) with respect to y we find the equation for the dashed line

$$K_{yy} = \frac{1}{2} K_{yyyy}^* \delta_y^2 + (K_{yyyx}^* \delta_x + K_{yyy}^*) \delta_y + K_{yyx}^* \delta_x = 0 \quad (39)$$

and for the continuous one

$$K_{yyy} = K_{yyyy}^* \delta_y + K_{yyyx}^* \delta_x + K_{yyy}^* \quad (40)$$

which of course are valid in a small enough neighborhood around the crossing point. The main conclusion is that the real singularity associated with an “interesting” behaviour is a fold of the curve $y(x, \omega_y = 0)$. As long as K_{yyy} is small (as it is in our example) we expect that this singularity will be near the crossing point.

Figure 9. Some possible working points for the system. The bottom angle is on the vertical axis, the top angle on the horizontal one. The set of working points that we found with the help of the continuation procedure are inside the upper and lower boundaries which correspond to the bold lines. For a given admissible pair of boundary angles θ_0 , θ_1 we can read the value of the vertical load G_y (on the continuous contour lines) and of the $1 - x$ parameter (the dotted contour levels). As an example, it is possible to obtain a good working point for a blade with $\theta_0 = 60$ and $\theta_1 = 0$ by setting $G_y = -2$ and $1 - x = 0.04$.

A pitchfork singularity is the one which is usually used to describe Euler buckling of a beam under compression. In that case the buckling is associated clearly with the breaking of a symmetry which is not present in our case. But to completely understand in what sense the “interesting” working point we described can be associated to a “buckling” phenomena it would be better to have a connection with some kind of geometrical peculiarity of the blade’s profile associated with the two different “buckled” configurations. Our conjecture, supported by some numerical calculations, is that in the bistable regime the two configurations differ in the presence of a point where the curvature changes its sign.

2.1.7. Uniform Curvature At the working point the blade is bent to a profile determined by Equations (6) and (7). We are interested in configurations with optimally distributed stress. There are two main reasons for this. First, a blade with a uniform stress has a higher safety limit. Second, in the optimized case for a given load the maximal stress is reduced, which means that the intensity of creep and creak noise is also reduced (special alloys such as properly treated Maraging do not show an increase of creeping if the stress is increased).

The dominant part of the stress is connected to the curvature radius R of the blade, so for an optimized configuration this quantity should be independent of ξ . For the “old” GAS filter this is not possible[Bertolini *et al* 1999] because the boundary conditions imply zero curvature on the blade’s tip. In the monolithic case we can substitute in the equilibrium equations (6),(7) the uniform curvature solution $\theta = \theta_0 + \xi(\theta_1 - \theta_0)$, obtaining an equation for $\gamma(\xi)$ which can be explicitly solved:

$$\gamma(\xi) = \frac{(\theta_1 - \theta_0)^2}{(\theta_1 - \theta_0)^2 - G_y[\sin \theta(\xi) - \sin \theta_0] - G_x[\cos \theta(\xi) - \cos \theta_0]}, \quad (41)$$

where $\gamma(\xi)$ must be always positive in order to describe a physically acceptable solution.

It is evident that the shape depends explicitly on the G_i parameters. This means that the blade profile should be tailored to the chosen working point, and it is probably very difficult to do this in practice. The solution we found tells us only that the uniform curvature solution is an equilibrium position of the system. To be practically useful this configuration must be stable, and with a low enough vertical resonance frequency.

Care must be taken in writing the equations for the continuation procedure. The dependence of the blade shape from the parameters G_i should be considered in the equations described in Appendix A only to lowest order. In fact, higher order auxiliary functions $\theta_{(k,l)}$ describe physically the behavior around the working point of a well defined blade with fixed shape.

We performed extensive numerical explorations of the constant curvature solution space, trying to find a critical point, but without success. It seems that the condition of constant curvature is not compatible with the low vertical stiffness property we want.

After the discussion at the end of Subsection 2.1.6 this conclusion is very reasonable. We associated the critical point responsible for the vanishing stiffness with a transition

between two states which differ for the number of points where the curvature goes to zero. This means that near the critical point a constant curvature solution should approach a “flat” configuration, but this is possible only when $\theta_0 = \theta_1$ and the load is parallel to the blade’s direction. This case can be studied analytically, and is incompatible with a vanishing stiffness.

We take the negative result of our numerical experiments as a confirmation of our conjecture about the “buckling-type” nature of the critical point.

3. Conclusion and Perspectives

The main purpose of this article was a study of the low frequency behavior of a geometric antispring. We identified a singularity in the space of tunable parameters (load and geometrical constraints) which is associated with a vanishing vertical stiffness.

Nonlinearities do not seem to be big problems for the kind of application we have in mind, where the ratio between the expected motion’s amplitude and the blade’s length L is very small. Cubic nonlinearities can be eliminated by tuning the working point.

About thermal stability, our conclusion is that it is possible in principle to reduce the sensitivity of the system to temperature variations. The tuning can be done by carefully choosing the materials, the geometry and the working point. However, the quantities involved typically change very rapidly near the critical point, and this means that at the end the only possibility will be a case by case trial and error adjustment procedure, probably delicate and difficult.

We have not yet performed an extensive exploration of the space of possible configurations. We suspect that this space is very large indeed, and the possibility of some optimization of the blade’s behavior should not be neglected, if needed. Our next step will be the study of the behavior of the coefficients $K_{..}^*$ which describe the system around the critical point in this space. We plan also to study the system in the high frequency regime, including mass effect and internal modes.

The numerical model described in the article has been implemented in a set of codes based on the continuation algorithms provided by the AUTO2000 library. This code will be used in the future to study and optimize special configurations, and is available on request.

Appendix A. First and second order response around the working point

In principle information about the coefficients of the effective potential can be recovered by numerical differentiation of the series $G_i(x, y)$ obtained with the continuation method. However, this method is very inaccurate especially if higher order coefficients are needed. For this reason we used a different approach to perform this task, which is basically a perturbative expansion of the external parameters around a given solution of Equation (6) and (7).

There are many ways to choose independent parameters, and here we describe a possibility which is simple from a computational point of view.

The more direct approach is to choose as independent parameters the external loads G_i , and to introduce a small perturbation ϵ_i around a reference point by writing $G_i = G_i^{(0)} + \epsilon_i$. For a given quantity C we introduce the notation $C_{l,m}$ to identify the coefficients of its expansion in powers of ϵ_i . For example, we formally write the solutions of the perturbed static problem as

$$\theta(\xi) = \sum_{k,l} \epsilon_x^k \epsilon_y^l \theta_{k,l}(\xi). \quad (\text{A.1})$$

By direct substitution we can easily obtain up to a given order the equations for $\theta_{k,l}$ and $p_{k,l}$. The equations for $\theta_{0,0}$ and $p_{0,0}$ are of course exactly the (6) and (7), with the same boundary conditions (8), and load parameters $G_i = G_i^{(0)}$. In the general case we can write

$$\frac{dp_{k,l}}{d\xi} = -\Re \left\{ \left[(iG_x^{(0)} + G_y^{(0)}) \eta_{k,l} + i\eta_{k-1,l} + \eta_{k,l-1} \right] e^{i\theta_{0,0}} \right\} \quad (\text{A.2})$$

$$\frac{d\theta_{k,l}}{d\xi} = \gamma(\xi) p_{k,l} \quad (\text{A.3})$$

where $\eta_{k,l}$ are the expansion coefficient for $e^{-i\theta_{0,0}} e^{i\theta}$ which are

$$\eta_{k,l} = e^{-i\theta_{0,0}} \frac{1}{k!} \frac{1}{l!} \frac{\partial^{k+l}}{\partial \epsilon_x^k \partial \epsilon_y^l} e^{i\theta} \Big|_{\epsilon_i=0} \quad (\text{A.4})$$

when $k, l \geq 0$ and zero otherwise. Note that the equation for $p_{k,l}$ depends linearly on $\theta_{k,l}$ but nonlinearly on $\theta_{k',l'}$ with $k' < k$ or $l' < l$. For example, at the first order we obtain

$$\eta_{1,0} = i\theta_{1,0}, \quad (\text{A.5})$$

$$\eta_{0,1} = i\theta_{0,1}, \quad (\text{A.6})$$

and at the second order

$$\eta_{2,0} = i\theta_{2,0} - \frac{1}{2}\theta_{1,0}^2, \quad (\text{A.7})$$

$$\eta_{1,1} = i\theta_{1,1} - \theta_{0,1}\theta_{1,0}, \quad (\text{A.8})$$

$$\eta_{0,2} = i\theta_{0,2} - \frac{1}{2}\theta_{0,1}^2. \quad (\text{A.9})$$

We also need boundary conditions for the newly generated differential equations. These can be simply obtained by imposing that the angles at the top and at the bottom do not change during the perturbation, obtaining simply

$$\theta_{k,l}(0) = \theta_{k,l}(1) = 0 \quad (\text{A.10})$$

for $k > 0$ or $l > 0$. The coordinates of the blade's tip can also be expressed as a function of the $\theta_{k,l}$ variables. By direct substitution in Equations (10) and (5) we get

$$x + iy = \sum_{k,l} \epsilon_x^k \epsilon_y^l \int e^{i\theta_{0,0}} \eta_{k,l} d\xi \quad (\text{A.11})$$

Using these relations we can obtain all the physical predictions we need. For example, the effective stiffness matrix of the blade's tip (the K_{ij} piece in the effective potential) is proportional to the coefficient which connects the first order variation of the coordinate with the load variation. Explicitly writing first order terms we get:

$$(K^{-1})_{xx} = \frac{\partial x}{\partial G_x} = x_{1,0} = - \int \theta_{1,0} \sin \theta_{0,0} d\xi \quad (\text{A.12})$$

$$(K^{-1})_{yy} = \frac{\partial y}{\partial G_y} = y_{0,1} = \int \theta_{0,1} \cos \theta_{0,0} d\xi \quad (\text{A.13})$$

$$(K^{-1})_{xy} = \frac{\partial x}{\partial G_y} = x_{0,1} = - \int \theta_{0,1} \sin \theta_{0,0} d\xi \quad (\text{A.14})$$

$$(K^{-1})_{yx} = \frac{\partial y}{\partial G_x} = y_{1,0} = \int \theta_{1,0} \cos \theta_{0,0} d\xi \quad (\text{A.15})$$

The symmetry in the indices is not apparent, but it can be demonstrated, for example, assuming that the equations for $\theta_{k,l}$ up to a given order can be obtained by minimizing a potential energy.

An alternative useful expansion can be obtained by perturbing $G_y = G_y^{(0)} + \epsilon_y$ with fixed x . Now the expansion of a generic quantity is

$$C = \sum_l \epsilon_y^l C_l \quad (\text{A.16})$$

and G_x is no more an external parameter, but a Lagrange multiplier which must be determined order by order to satisfy the constraint (10).

Appendix B. Exact solution for constant width blade

If the blade width is constant we can rewrite the potential in Eq. (3) as

$$\tilde{U} = \int_0^1 \left\{ \frac{1}{2} \left(\frac{d\beta}{d\xi} \right)^2 - G(1 - \cos \beta) \right\} d\xi \quad (\text{B.1})$$

where $G = \sqrt{G_x^2 + G_y^2}$, $\beta = \theta - \psi$, $\cos \psi = -G_x/G$ and $\sin \psi = -G_y/G$. This is formally the Lagrangian of a pendulum which evolves in the “time” ξ , whose solution is exactly known in term of elliptic integrals. We can write the solution as

$$\sin \frac{\beta(\xi)}{2} = \text{sn} \left(\frac{\sqrt{G}}{k} \xi + \phi, k \right) \quad (\text{B.2})$$

where $\text{sn}(x, k)$ is a Jacobi elliptic function and k, ϕ two integration constants that can be determined by imposing the boundary conditions ($k > 0$). It is easy to eliminate ϕ , and we get the condition

$$\Gamma = \sigma_1 \text{sn}^{-1} \left[\sin \frac{\beta_1}{2}, k \right] - \sigma_0 \text{sn}^{-1} \left[\sin \frac{\beta_0}{2}, k \right] - \frac{\sqrt{G}}{k} + (4m + \sigma_0 - \sigma_1)K(k) = 0 \quad (\text{B.3})$$

where m is an arbitrary integer, $K(k)$ the complete elliptic integral of the first kind and $\sigma_i = \pm 1$. We are interested in particular in the coordinates of the blade's tip, which can be written as

$$\begin{pmatrix} x(1) \\ y(1) \end{pmatrix} = \frac{k}{\sqrt{G}} R(\psi) \begin{pmatrix} \frac{\sqrt{G}}{k} \left(1 - \frac{2}{k^2} \right) + \frac{2}{k^2} \left[f \left(\frac{\beta_1}{2}, k \right) - f \left(\frac{\beta_0}{2}, k \right) \right] \\ \sigma_1 \sqrt{1 - k^2 \sin^2 \left(\frac{\beta_1}{2} \right)} - \sigma_0 \sqrt{1 - k^2 \sin^2 \left(\frac{\beta_0}{2} \right)} \end{pmatrix} \quad (\text{B.4})$$

where $f(\phi, k)$ is the elliptic integral function of the second kind, and $R(\psi)$ the matrix which rotates a bidimensional vector by an angle ψ . We also have to take into account that during a variation of the parameters the boundary conditions stay fixed. This gives us a relation, which can be obtained by imposing $d\Gamma(1) = 0$. Another constraint is that the coordinate x of the blade's tip does not change during the variation, which is equivalent to imposing $dx(1) = 0$. The last step is to evaluate the differential $dy(1)$: in this way we get three linear relations between $dy(1)$, dG_x , dG_y and dk that we can use to express

$$dy(1) = \chi dG_y \quad (\text{B.5})$$

where χ is a function of the working point, and $\chi \rightarrow \infty$ when the vertical stiffness of our constrained blade goes to zero. After some algebraic multiplication it is easy to see that we can express χ as

$$\chi = \begin{vmatrix} \frac{\partial \Gamma}{\partial G} & \frac{\partial \Gamma}{\partial \psi} & \frac{\partial \Gamma}{\partial k} \\ \frac{\partial x}{\partial G} & \frac{\partial x}{\partial \psi} & \frac{\partial x}{\partial k} \\ \frac{\partial y}{\partial G} & \frac{\partial y}{\partial \psi} & \frac{\partial y}{\partial k} \end{vmatrix} \begin{vmatrix} \frac{\partial \Gamma}{\partial G} & \frac{\partial \Gamma}{\partial \psi} \\ \frac{\partial x}{\partial G} & \frac{\partial x}{\partial \psi} \end{vmatrix}^{-1} \quad (\text{B.6})$$

where all the quantities are evaluated at $\xi = 1$. In order for χ to be divergent there are two possibilities: some of the partial derivatives inside the determinants could be divergent, or the 2×2 determinant could go to zero. Moreover, in the first case, as the determinant depends linearly on its elements, the only possibilities are a divergence of partial derivatives which appears in the 3×3 but not in the 2×2 determinant.

We used the analytical solution for cross-checking purposes and as a convenient starting point for the continuation procedure. By introducing an interpolation parameter it is easy to continue the blade profile from the constant width case to the specific case we are interested in.
